Unity Power Factor Operation of Indirect Matrix Converter Tied to Unbalanced Grid

Mahmoud Hamouda, Handy Fortin Blanchette, Member, IEEE, and Kamal Al-Haddad, Fellow, IEEE

Abstract—This paper presents a new control method for Indirect Matrix Converter operating under unbalanced grid voltages. The proposed method aims to achieve balanced output voltages as well as a near unity input power factor operation. First, an opportunity reference current accurately generated, and a proportional integral resonant controller are designed in a dq reference frame that is synchronized with the positive sequence of the grid voltages so as to achieve a perfect tracking of input reactive power reference. Then, a real-time estimator of the grid voltages is developed with the aim to provide balanced output voltages; therefore an almost constant active virtual dc-link voltage is developed with the aim to provide reactive power reference. Experimental results are presented to verify the feasibility and effectiveness of the proposed control method.

Index Terms—matrix converters, resonant controllers, space vector modulation (SVPWM), unbalanced grid voltages, power factor correction, active rectifier, grid-tied converter

NOMENCLATURE

- $d_{a}, d_{b}, d_{c}$ Duty cycles applied to estimate the dc-link voltage.
- $d_{1P}, d_{2P}$ Duty cycles applied to synthesize the output voltage space vector.
- $d_{1R}, d_{2R}$ Duty cycles applied to synthesize the input current space vector’s direction.
- $E_{a,b,c}$ Grid voltage space vector.
- $\tilde{E}$ Conjugate of $E$.
- $E^+, E^-$ (+) sequence of grid voltage space vector.
- $E^+, E^-$ Peak value of $E_{a,b,c}$ (+) and (-) sequences.
- $E_d^+, E_q^+$ d-q components of (+) sequence of grid voltages expressed in the positive synchronous frame.
- $E_d^-, E_q^-$ d-q components of (-) sequence of grid voltages expressed in the positive synchronous frame.
- $E_{a,b,c}^\prime$ Lagging orthogonal voltages of $E_{a,b,c}$.
- $\tilde{E}$ A space vector equivalent to $E_{a,b,c}^\prime$.
- $i_{a,b,c}$ d-q components of $E_{a,b,c}$.
- $i_{ma,mb,mc}$ Instantaneous input currents in abc frame.
- $\tilde{I}_m$ Input current space vector.
- $\tilde{I}_m$ Instantaneous line currents in abc frame.
- $I^*$ Line current space vector.
- $I^*$ Conjugate of $I$.
- $i_{a,b,c}^+, i_{a,b,c}^-$ d-q components of line currents (+) sequence.
- $i_{d,q}^+, i_{d,q}^-$ d-q components of line currents (-) sequence.
- $i_{a,b,c}^* d-q$ components of $i_{a,b,c}$.
- $i_{ma,mb,mc}^*$ d-q components of input currents $i_{ma,mb,mc}$.
- $K_i$ The sector’s number where $\tilde{I}_m$ is lying.
- $\eta$ Gain of resonant term.
- $K_{ damp}, L, c, r$ Proportional and integral gains of the PI controller.
- $p_{in}$ Damping gain of resonant term.
- $Q_{ damp}$ Input filter’s inductance, capacitance, and resistance.
- $Q_f$ Quality factor of resonant term.
- $Q_{ in}$ Quality factor of the input filter.
- $Q_{ ref}$ Grid converter exchanged reactive power.
- $Q_{ in}$ Average reactive power reference.
- $s$ Laplace variable.
- $(\tilde{S}_c)_{T_c}$ Averaged switching function of the grid side converter.
- $T_c$ Switching period.
- $(\tilde{V}_{dc})_{T_c}$ Estimated average value of the dc-link voltage.
- $V_{ma,mb,mc}$ Voltages across the input filter capacitors.
- $V_{md}$ Direct component of $V_{ma,mb,mc}$.
- $\varphi^+, \varphi^-$ Initial phase angles of (+) and (-) negative sequences of line currents.
- $\varphi_1$ Phase angle between $\tilde{E}^+$ and $\tilde{I}_m$.
- $\theta_1$ Phase angle of $\tilde{I}_m$ within its operating sector.
- $\omega_1$ Initial phase angle of grid voltages (+) sequence.
- $\omega_0$ Grid voltage’s angular frequency.
- $\omega_r$ Input filter’s resonant angular frequency.
- $\omega_r$ Resonant angular frequency of the resonant controller.

Manuscript received September 26, 2014; revised January 16, 2015; accepted March 26, 2015. Date of publication XXXX; date of current version XXXX. This work was supported in part by NSERC, Canada Research Chair in Electric Energy Conversion and Power Electronics CRC-EECP, ETS de Montréal.

I. INTRODUCTION

Matrix Converters are direct AC/AC power conversion devices that are capable of generating variable frequency and amplitude voltages at their output terminals without using bulky and limited lifetime electrolytic capacitors. This important feature allows for the design of high reliability high power density converters. The Indirect Matrix Converter (IMC) depicted in Fig.1, has two major components namely; the four-quadrant current source rectifier called "grid side converter", and the voltage source inverter referred to as "load side converter". Similar to the direct conventional single stage converter, this topology can achieve near sinusoidal line/load currents, controllable input power factor, regeneration capability, etc. Moreover, it has a more secure and less complex commutation process as well as a simple clamp circuit [1]. Compared to the conventional back to back topology, no additional sensors or regulation loops are required to control the voltage across the dc-link [2] [3] [4].

Over the last years, several research works have showed that matrix converters are suitable for various modern industrial applications such as distributed power generation systems [5] [6], multi-drive systems [7], variable speed drives [8] [9], wind energy [10], unified power flow controller (UPFC) [11], etc. However, like the conventional grid-tied converters, the expected performances (THD of line currents, THD of output voltages, maximum voltage transfer ratio) of Matrix Converters are considerably decreasing when operating under unbalanced grid voltages. It has been shown in [12] that the input voltage imbalance gives rise to low-order harmonics in the output voltages and input currents waveforms. Therefore, low-frequency ripples are provided in the waveform of the demanded instantaneous active power and the reactive power exchanged with the utility.

On the other hand, the input LC filter of the Matrix Converter introduces an inherent phase shift between the line currents \(i_a, i_b, i_c\) and grid voltages \(E_{a,b,c}\) which decreases the input power factor as deeply discussed in references [13] [14] [15] [16] [17]. The resulting reactive power demanded from the power grid will therefore give rise to unwanted power losses in the transmission and distribution lines. When the supply voltages are unbalanced, the power grid becomes more sensitive toward the reactive power demand since the latter includes in addition to the dc component low-frequency ripple components which inherently enlarges the amount of the aforementioned losses. Note that the Matrix Converter has the capability to help in supporting the grid voltages by injecting the appropriate amount of reactive power as has been widely recommended by recent grid codes [18] [19] [20]. In this case, the converter needs to operate with a non-unity input power factor where the line currents are leading their corresponding voltages by a positive phase shift. This operation mode is however not the best suited one since it lowers the maximum voltage transfer ratio and consequently the maximum active power to be transferred to the load. Accordingly, the unity input power factor operation is the most opportune operating mode to be considered when the converter is connected to either balanced or unbalanced grid.

Note also that the minimization of the reactive power exchange when the converter is connected to a distorted AC supply has been considered as a key constraint in [21].

Different control methods were proposed in the literature to enhance the performance of Single Stage/ Indirect Matrix Converters operating under unbalanced grid voltages. In [22] [23] [24], several dynamic space vector modulations of the input currents are proposed to enhance their quality and cancel low-order harmonics that are caused by the grid voltages imbalance. However, the impact of these techniques on balancing the load currents was not discussed. In [25], a modulation technique that determines the opportune amplitude and phase angle of the negative sequence of the line currents has been proposed with the aim to improve the quality of the line and load currents respectively. In [26], the authors proposed a modified calculation method of the grid voltages phase angle. This latter was combined with the conventional space vector modulation technique with the aim to enhance the quality of the output voltage waveform. In [27], the authors proposed three modulation methods for the Matrix Converter based on three mathematical constructions of the rectifier and inverter modulation vectors. These methods achieve similar performance in terms of load current quality. As for the line current quality, the third method is a compromise between method I and II in terms of THD and third-order harmonic amplitude. In [28], a feed-forward compensation method of the input voltage imbalance was proposed. It has defined an appropriate unbalanced switching function of the grid side converter so as to cancel the low-order harmonics contents in the voltage across the virtual dc-link. Consequently, balanced output voltages are provided at the load side. In, [29] the authors proposed an active compensation method that uses the clamp capacitor so as to provide balanced output voltages and preserve the maximum value of the voltage transfer ratio.

Fig.1 Power circuit of an Indirect Matrix Converter
A feed-forward compensation method based upon measurement of the instantaneous grid voltages was proposed in [30] with the aim to provide balanced output voltages. In [31] a predictive control algorithm is applied to the converter feeding an induction motor. It has been shown that the proposed strategy presents satisfactory behavior even under unbalanced grid voltages.

On the other hand, the input power factor correction under balanced grid voltages operation has been addressed by many research works [17] [15] [13] [32]. The behavior of the converter has also been investigated under distorted grid voltages [21] [33]. Such a disturbance of the grid voltage is however out of the scope of this work.

This paper proposes an advanced control method of Indirect Matrix Converter operating under unbalanced grid voltages. The proposed controller is designed with the aim to achieve two main goals: 1) the converter should provide balanced output voltages and therefore an almost low-frequency-ripple free active power (constant active power) is demanded from the grid. 2) A near unity input power factor operation should be achieved. The second goal is the main novelty of the paper that has not been addressed by the previous research works.

The manuscript is organized as follows: Section II provides a detailed definition of the instantaneous active and reactive powers under unbalanced grid voltages. The proposed control method of the converter operating under unbalanced grid voltages is explained in sections III and IV respectively. The maximum voltage transfer ratio that can be achieved. The second modulation method performs a dynamic modulation of the input displacement angle between the grid voltage vector and input current vector. This method provides sinusoidal but unbalanced line currents where the harmonic spectrum is reduced to one positive and one negative sequence components.

Therefore, according to the second method, sinusoidal and unbalanced line currents can be provided by the Matrix Converter such that:

\[
\bar{I} = I^+ e^{j(\omega_1 t + \varphi^+)} + I^- e^{j(-\omega_1 t - \varphi^-)}
\]  

(2)

\( I^+ \) and \( I^- \) are the peak values of the positive and negative sequences of the line currents; \( \varphi^+ \) and \( \varphi^- \) are their initial phase angles. The instantaneous input active power supplied from the grid to the converter is derived by taking the real part of the complex power such that:

\[
p_{in} = \frac{3}{2} \text{Real}(\bar{E} \bar{I})
\]  

(3)

Equation (3) shows that the instantaneous active power at the grid connection point consists of a constant term that represents the average value \( \bar{P}\) of the active power as well as cosine and sine terms of twice the grid frequency that are caused by the grid voltage imbalance. Assume the converter’s losses are neglected; therefore the ripple terms can be cancelled simply by providing balanced output voltages as will be explained in section IV. On the other hand, it has been adopted in recent literature that the instantaneous reactive power under unbalanced and non-sinusoidal grid voltages can be described in terms of virtual AC voltages that lag the actual grid voltages by 90° [37] as:

\[
Q_{in} = E'_{a}i_a + E'_{b}i_b + E'_{c}i_c
\]  

(4)

\( E'_{a,b,c} \) are the instantaneous voltages that lag the actual grid voltages by 90°; \( i_{a,b,c} \) are the instantaneous line currents. The reactive power is therefore equivalent to the real part of a quadrature complex power and can be defined as follows:

\[
Q_{in} = \frac{3}{2} \text{Real}(\bar{E} \bar{I})
\]  

(5)

In a similar manner, one can observe that besides the constant term, a cosine and sine terms of twice the grid frequency appear in the instantaneous input reactive power waveform. In order to achieve a near unity input power factor operation, one should perform an accurate control of the average reactive power as will be explained in the following section.
III. INPUT POWER FACTOR CONTROL VIA THE GRID SIDE CONVERTER

A. Reactive Current Reference Calculation

The input power factor control requires the computation of the opportune line currents phase angles. Indeed, according to the first term of (5), the average reactive power that the converter can exchange with the grid depends on the initial phase angles \( \varphi^+ \) and \( \varphi^- \). Its reference \( Q_{0,ref}^{\text{in}} \) is therefore defined as:

\[
Q_{0,ref}^{\text{in}} = \frac{3}{2} \left[ -E^+ I^+ \sin(\varphi^+_\text{ref}) - E^- I^- \sin(\varphi^-_\text{ref} - \theta^-) \right] \tag{6}
\]

Where, \( \varphi^+_\text{ref} \) and \( \varphi^-_\text{ref} \) are the initial phase angles references of the positive and negative sequences of the line currents. The expression of \( \varphi^-_\text{ref} \) is therefore derived as follows:

\[
\sin(\varphi^-_\text{ref}) = -\frac{2}{3} \frac{Q_{0,ref}^{\text{in}}}{E^+ I^+ - E^- I^- \sin(\varphi^-_\text{ref} - \theta^-)} \tag{7}
\]

On the other side, assume that the oscillating components of the input active power (two last terms of (3)) are perfectly compensated as will be discussed in section IV. The input active power (two last terms of (3)) are perfectly compensated as will be discussed in section IV. The first term of (5), the average reactive power can be expressed as:

\[
\sin(\varphi^+_\text{ref}) = -\frac{2}{3} \frac{Q_{0,ref}^{\text{in}}}{E^+ I^+ - E^- I^- \sin(\varphi^+_\text{ref} - \theta^+)} \tag{8.a}
\]

According to equations (7) and (8a, 8b), the opportune references \( \varphi^+_\text{ref} \) and \( \varphi^-_\text{ref} \) that allow the converter to exchange \( Q_{0,ref}^{\text{in}} \) with the grid are determined as follows:

\[
\begin{align*}
\sin(\varphi^+_\text{ref}) &= -\frac{2}{3} \frac{Q_{0,ref}^{\text{in}}}{E^+ I^+ - E^- I^- \sin(\varphi^-_\text{ref} - \theta^-)} \\
\varphi^-_\text{ref} &= \varphi^+_\text{ref} + \theta^- - \pi
\end{align*} \tag{9.a}
\]

In order to achieve the control in a dq reference frame synchronized with the positive sequence of grid voltages, one can define the d-q components of grid voltages as well as the line currents such that:

\[
\begin{align*}
E_d &= E^+_d + E^-_d = E^+ + E^- \cos(-2\omega t - \theta^-) \\
E_q &= E^+_q + E^-_q = 0 + E^- \sin(-2\omega t - \theta^-)
\end{align*} \tag{10}
\]

\[
\begin{align*}
(I_d) &= I^+_d + I^-_d = I^+ \cos \varphi^+ + I^- \cos(-2\omega t - \varphi^-) \tag{11.a} \\
(I_q) &= I^+_q + I^-_q = I^+ \sin \varphi^+ + I^- \sin(-2\omega t - \varphi^-) \tag{11.b}
\end{align*}
\]

Substituting (8.a) and (9a, 9b) in (11.b) and rearranging, yields to the opportune references of positive and negative sequences of the line current reactive component as shown in (12.a) and (12.b) hereafter. A detailed mathematical development is given in the appendix.

\[
I^+_\text{q,ref} = \frac{2}{3} Q_{0,ref}^{\text{in}} \frac{E^+_d}{(E^+_d)^2 - (E^+_d - E^-_d)^2 + (E^-_d)^2} \tag{12.a}
\]

\[
I^-\text{q,ref} = \frac{E^-_d}{E^-_d} I^+_d + \frac{E^-_d}{E^-_d} I^-\text{q,ref} \tag{12.b}
\]

One can verify from (11.b) and (12a, 12b) that the q component of the positive sequence consists of a constant term \( (I^-\text{q,ref}) \) that depends only on the average reactive power reference. The negative sequence component \( (I^-\text{q,ref}) \) consists of a ripple term oscillating at twice the grid frequency. This ripple term depends on the dq components of positive and negative sequences of the grid voltages, as well as the dq components of the positive sequence of the line currents. These computed references are subsequently used as input references to the PIR control loop that is presented hereafter.

B. PIR Based Closed-loop Controller

With the aim to design the appropriate controller which allows an accurate tracking of the opportune current references computed by (12a) and (12b), we should first determine the dynamics of the line current reactive component \( i_q \). Using Kirchhoff laws, the reactive components of the line current and capacitor voltage can be expressed in a synchronous reference frame [17] [38]:

\[
\frac{d}{dt} i_q = -\frac{r}{L} i_q - \omega_i l_q \tag{13.a}
\]

\[
\frac{d}{dt} V_{mq} = -\omega_i V_{md} + \frac{1}{c} l_q - \frac{1}{c} i_{mq} \tag{13.b}
\]

As can be seen, the input current \( i_{mq} \) that is considered as the control-law does not appear explicitly in the first derivative of \( i_q \). By differentiating (13a) and using (13b), we can obtain the dynamics of \( i_q \) arranged in a canonical controllable form as shown in (13.c) where \( \omega_0 = \frac{1}{\sqrt{2}} \) is the input filter resonant angular frequency.

\[
\frac{d^2}{dt^2} i_q = -\frac{r}{L} \frac{d}{dt} i_q - \omega_0^2 l_q + \omega_0^2 i_{mq} \tag{13.c}
\]

Reporting (13.c) in Laplace domain, yields the transfer function described by (13.d) where \( Q_f = \frac{1}{r} \) is the input filter quality factor.

\[
i_q \left( \frac{s^2}{\omega_0^2} + \frac{1}{Q_f \omega_0} s + 1 \right) = \frac{i_{mq}}{\omega_0^2} \frac{1}{r} s l_d + \frac{1}{Q_f \omega_0} s E_q + \frac{1}{Q_f \omega_0} V_{md} \tag{13.d}
\]

The transfer function (13.d) shows that in addition to the control-law \( i_{mq} \), there exist one coupling and two disturbance terms that should be compensated by the regulator. The use of a PI regulator with an appropriate compensation of the additional terms found in (13.d) can perform a zero steady-state tracking error of the current reference only if the latter is.
a dc signal. Indeed, the key limitation of PI controllers is their inability to perform a perfect tracking of ac reference signals [39]. Accordingly, the ripple term existing in the current reference leads to amplitude and phase tracking errors if only a conventional PI regulator is used. Therefore, the PI controller is reinforced with a resonant term with a resonant frequency of twice the grid frequency. The transfer function of an ideal resonant controller is shown in equation (14), where $K_{HR}$ and $\omega_r = 2\omega_1$ are the gain and resonant angular frequency of the controller.

$$H_R(s) = \frac{K_{HR}}{s^2 + \omega_r^2}$$  \hspace{1cm} (14)

In open-loop, $H_R(s)$ provides an infinite gain at twice the grid frequency which ensures an accurate tracking (in closed-loop) of the double-frequency ripple component of the reference current, as well as disturbance rejection for signals pulsating at the resonant frequency. These benefits are achieved without affecting the high frequency stability [40] [41] [42]. However, the infinite gain and narrow bandwidth of the resonant controller may cause instability due to grid frequency deviation and discretization errors [43]. Hence, in order to avoid stability problems, a damped resonant term (15.a) is used instead of (14).

$$H_{R,damp}(s) = \frac{K_{HR}}{s^2 + \omega_r^2}$$ \hspace{1cm} (15.a)

$K_{damp}$ and $Q_{damp}$ are the damped gain and quality factor respectively. The transfer function defined in (15.a) provides a complete separation of the gain and bandwidth at resonant frequency such that:

$$\begin{align*}
H_{R,damp}(\omega = \omega_r) &= K_{HR}K_{damp} \\
BW(\omega = \omega_r) &= \frac{\omega_r}{Q_{damp}}
\end{align*}$$  \hspace{1cm} (15.b)

Moreover, one can observe that the standard ideal controller (14) is a particular case of (15.a) with $Q_{damp} \gg \omega_r$ and $K_{damp} = \frac{Q_{damp}}{\omega_r}$. Accordingly, the opportunite control-law $i_{mq}$ is determined by multiplying the error signal by the PIR controller transfer function and removing the coupling and disturbance terms of (13.d) which yields:

$$i_{mq} = \frac{\omega_r}{L_2} s i_q + \frac{1}{L_2} s E_q - \frac{\omega_1}{L_2} V_{md}$$  \hspace{1cm} (16.a)

As can be seen, equation (16.a) requires the calculation of the first derivative of $i_q$ and $E_q$, which reduces the accuracy of the control-law for real-time implementation. An equivalent expression to the first derivative of $E_q$ can be deduced from (10) as follows:

$$\frac{d}{dt} E_q = -2\omega_1 E_d$$  \hspace{1cm} (16.b)

On the other hand, the term $(s i_{sd})$ can be substituted by the mathematical equation that describes the dynamics of $i_d$ in the dq frame such that:

$$\frac{d}{dt} i_d = \frac{1}{L} i_{sd} + \frac{1}{L} E_d - \frac{1}{L} V_{md}$$  \hspace{1cm} (16.c)

Plugging equations (16.b) and (16.c) into (16.a), an equivalent expression of the control-law which is more suitable for real-time implementation is therefore obtained:

$$i_{mq} = \frac{K_p + \frac{K_I}{s} + \frac{K_{damp}}{s^2} + \frac{\omega_r}{Q_{damp}} s + \omega_1^2}{\omega_r} \left[ i_{q,ref} + i_{q,ref} - i_q \right]$$  \hspace{1cm} (16.d)

The control-law $i_{mq}$ is thereafter used to determine the opportune direction of the input current space vector such that:

$$\varphi_1 = tan^{-1} \left( \frac{i_{mq}}{i_{md}} \right)$$  \hspace{1cm} (17)

Where $\varphi_1$ is the instantaneous phase angle between the positive sequence of the grid voltage space vector ($E^+ = E^{+\phi\text{ial}}$) and the converter input current space vector namely $i_m$ as illustrated in Fig.2. Since $i_{md}$ is the direct component of modulated currents ($i_{m,mb,mc}$), therefore, it cannot be sensed with the aim to compute the instantaneous value of (17). By neglecting the power losses in the high frequency filter, one can assume the direct component $i_d$ is similar to $i_{md}$. Consequently, it can be used in equation (17) without loss of accuracy. Finally, the input current’s direction, that is determined according to (17), can be synthesized using the SVPWM technique which consists in impressing at each sampling period the two active vectors adjacent to $I_m$ with the opportune duty cycles, namely $d_{1R}$ and $d_{2R}$ as depicted in Fig.2.

C. Stability Analysis

The steady state and dynamic performance of the controller greatly depend on the gain of proportional, integral, and resonant terms.
Fig. 4a shows also that the phase margins obtained with both values of $K_{IR}$ are too small to ensure a robust stability. A further decrease of $K_{IR}$ is not suitable since it will worsen the accuracy at steady-state operation. The only permissible solution is therefore to decrease the proportional gain $K_p$. Fig. 4b displays the Bode diagrams obtained with $K_I = K_{IR} = 15$ and $K_p = 0.03$. The obtained phase margin is theoretically greater than 40°. However, it is worthy to point out that the above analysis was done without considering the effect of the delays caused by the sampling phenomenon as well as by the current and voltage transducers. Equation (20) gives a more realistic open-loop transfer function including one sampling period delay $(e^{-T_s})$.

$$G(s) = e^{-T_s} \left[ K_p + \frac{K_I}{s} + \frac{K_{IR}}{s^2 + \frac{\omega_r}{Q_d} s + \omega_r^2} \right] \frac{1}{s^2 + \frac{\omega_d}{Q_d} s + \frac{1}{Q_f} + 1} \frac{1}{s^2 + \frac{1}{Q_f} + 1}$$

The corresponding Bode plot of Fig. 4c (black curve) shows clearly that the phase margin becomes smaller and thereby is not sufficient to ensure a robust stability. It is therefore obvious to conclude that a lower value of $K_p$ that provides a gain below the 0 dB line is mandatory to avoid the stability problem at the resonant frequency of the filter. Fig. 4c (gray curve), shows the Bode plot for $K_p = 0.01$; as compared to the previous case (black curve), it is clear that the filter gain at resonance frequency is well damped so that the gain curve will never cross over the 0 dB line at this critical frequency. Moreover, the gains at the dc and the controller’s resonant frequencies remain unchanged implying that no negative impact will occur on the steady state error. It was experimentally tested that a suitable value of the proportional gain below 0.03 is $K_p = 0.01$. This value leads to a satisfactory performance for line current THD which is an important constraint.

D. Extension to Four-Wire Configuration

As compared to the three-wire converters structures, the four-wire configuration introduces a zero-sequence current path which is helpful to achieve a better power control performance [20]. Therefore, to extend the proposed control-theory to the four-wire configuration, it is mandatory to design an additional loop so as to enable the controllability of the zero-sequence current flowing through the neutral point.
The authors underline that, to their best knowledge, the most commonly used Matrix Converters topologies are connected to grid through a three-wire system. The four-wire system has been adopted in case of unbalanced load which is connected to grid through a three-wire system. The four-wire topology named the Four-Leg Indirect Matrix Converter [44].

IV. CONTROL OF OUTPUT VOLTAGES AND ACTIVE POWER

For the sake of simplicity, the converter’s losses are assumed to be neglected. Therefore, if balanced output voltages and currents are provided at the load side of the converter, the input active power is inherently free of double-frequency ripple components. For this purpose, a straightforward method will be presented hereafter so as to provide balanced output voltages when the converter is tied to an unbalanced grid. Therefore, a real-time estimator of the dc-link voltage is developed based upon the measurement of instantaneous grid voltages as well as an average switching function of the grid side converter.

As an example, assume the input current reference vector \( \vec{I}_{m} \) is residing within sector 1 of the complex plane as illustrated in Fig.2. In this situation, the upper switch of phase-leg \( a \) is turned on over the full switching period while the lower switches of phase-legs \( b \) and \( c \) are modulated with duty cycles \( d_{1b} \) and \( d_{2b} \) respectively. The remaining power devices are switched off. An average switching function \( \langle S_O \rangle_{\tau_c} \) of the grid side converter can thereafter be defined within a switching period \( (T_c) \) as given in equation (21.a)

\[
\langle S_O \rangle_{\tau_c} = \frac{2}{3}(1 - a \, d_{1b} - a^2 \, d_{2b}) \tag{21.a}
\]

Equation (21.a) in turn can be generalized for the six possible positions of the input current space vector \( \vec{I}_{m} \) in the complex plane as shown in equation (21.b), where \( d_{a,b,c} \) are duty cycles assigned to phase-legs \( a, b, \) and \( c \).

\[
\langle S_O \rangle_{\tau_c} = \frac{2}{3}(d_a + a \, d_b + a^2 \, d_c) \tag{21.b}
\]

On the other hand, let \( \bar{y}_l \) be defined as the instantaneous phase angle of \( \vec{I}_{m} \) within its operating sector as seen in Fig.2.

\[
\bar{y}_l = \omega_l t - (K_l - 1) \frac{\pi}{3} + \frac{\pi}{6} + \varphi_l \tag{22.a}
\]

In (22.a) \( K_l \) is the sector number where \( \vec{I}_{m} \) is lying. In this case, the duty cycles \( d_{1b} \) and \( d_{2b} \) can be expressed as a function of \( \bar{y}_l \) such that [4]:

\[
d_{1b} = \sin\left(\frac{\pi}{6} - \bar{y}_l\right), \quad d_{2b} = \frac{\sin(\bar{y}_l)}{\cos(\pi/6 - \bar{y}_l)} \tag{22.b}
\]

Therefore, equation (21.b) can be rewritten as follows:

\[
\langle S_O \rangle_{\tau_c} = \frac{1}{\cos[\omega_l t - (K_l - 1) \frac{\pi}{3} + \varphi_l]} e^{j(\omega_l t + \varphi_l)} \tag{23}
\]

It follows that the average value of the dc-link voltage can be expressed as:

\[
\langle V_{dc} \rangle_{\tau_c} = \frac{3}{2} \text{Real} \left[ \langle S_O \rangle_{\tau_c} \hat{E}^* \right] = \frac{3}{2} E^* \cos \varphi_l + E^* \cos(2\omega_l t + \theta^* + \varphi_l) \tag{24}
\]

\( \hat{E}^* \) is the conjugate space vector of the grid voltages. \( \varphi_l \) is the instantaneous phase angle between the positive sequence of the grid voltage space vector and \( \vec{I}_{m} \) that is computed in real time by the PIR controller as explained above in section III/B. Consequently, the real-time estimator should operate downstream of the PIR based control loop. On the other hand, one can observe that the nominator of the estimated dc-link voltage (equation (24)) includes a double-frequency ripple term due to the grid imbalance. Such term that appears in the denominator is due to modulation scheme of the grid side converter. Note also that the upper term of (24) needs less computational burden as compared to the lower term of the same equation, since it avoids using trigonometric functions and the division operator. Therefore, the real-time implementation of the dc-link voltage estimator is based on the upper term of (24) where the value of \( \langle S_O \rangle_{\tau_c} \) is updated according to (21.b).

Assume now the dc-link voltage is constant within a sampling period and is equal to its average value. A balanced output voltage system can therefore be provided at the load side simply by impressing the active vectors of the load side
converter by an unbalanced system of duty cycles as shown in (25) where \(d_{11}\) and \(d_{21}\) stand for the applied duty cycles of the two active vectors adjacent to the reference space vector \(\vec{V}_{o, ref}\). The latter is equivalent to the balanced output voltages \(V_a\), \(V_b\), and \(V_c\). \(V_o\) and \(\theta_o\) are the amplitude and instantaneous phase angle within its operating sector of the reference space vector \(\vec{V}_{o, ref}\) as depicted in Fig.5.

\[
d_{11} = \sqrt{3} \frac{V_o}{(V_{ac})^2} \sin \left( \frac{\pi}{3} - \theta_o \right) ; \quad d_{21} = \sqrt{3} \frac{V_o}{(V_{ac})^2} \sin(\theta_o) \quad (25)
\]

Fig.6 shows a general block diagram of the proposed controller. A multiple reference frame PLL (MRF-PLL) is implemented so as to achieve a perfect synchronization with the positive sequence of the grid voltages as well as a minimized ripple in the estimated phase angle waveform. The implementation of reactive current references \(I_{r, ref}^+\) and \(I_{r, ref}^-\) according to (12.a-b) requires the real-time computation of signals \(E_d^+, E_q^+, E_d^-, E_q^-\), and \(I_d^+, I_q^+, I_d^-, I_q^-\), \(E_d^+, E_q^+, E_d^-, E_q^-\) are directly extracted from the MRF-PLL block while a low-pass filter is used to extract \(I_{r, ref}^+\) from the signal \(i_d\). Once the current references are determined, the control-law \(i_{g, ref}\) and the instantaneous phase angle \(q_1\), are computed according to (16.d) and (17). This allows performing the SVPWM scheme of the grid side converter and also the estimation of the dc-link voltage according to the upper term of (24) and (21.b). Therefore the SVPWM of the load side converter is performed according to (25). Finally, the block “switching pattern distribution” generates the appropriate gating pulses for the grid side and load side parts of the Indirect Matrix Converter.

V. MAXIMUM VOLTAGE TRANSFER RATIO

Assume firstly that the load side converter operates as a conventional voltage source inverter supplied by a constant dc source. The relationship between the amplitude of the output voltage fundamental component and the dc source voltage is defined as a function of the inverter modulation index \(M_i\) such that:

\[
V_o = M_i \frac{V_{dc}}{2} \quad (26)
\]

It is well known that when the output voltages are modulated with the SVPWM scheme, the maximum value of \(M_i\) is \(M_{imax} = 1.55\). On the other hand, Fig.7 displays the grid vector voltage locus where \(E^+ = E^* e^{j\omega t}\) is the vector equivalent to the positive sequence component and rotating counterclockwise; \(E^- = E^* e^{j(\omega t - \theta^*)}\) is the vector equivalent to the negative sequence component and rotating clockwise.

Fig.5 Synthesis of \(V_{o, ref}\) vector using SVPWM method

Fig.6 Simplified schematic diagram of the control-law
The grid voltage vector $\vec{E}$ is rotating in an elliptical trajectory because of the negative sequence component. Therefore, the amplitude of $\vec{E}$ is time varying while being bounded by the amplitudes of the major and minor axes. Its minimum value is equal to $(E^+ - E^-)$ and occurs when $E^+$ and $E^-$ have the same direction but opposite sense i.e.

$$\omega_i t = -\omega_i t - \theta^- + 2k\pi \quad (k = 1, 3, \ldots)$$

(27)

The maximum amplitude of $\vec{E}$ is equal to $(E^+ + E^-)$ and occurs when $E^+$ and $E^-$ are oriented toward the same direction and sense i.e.

$$\omega_i t = -\omega_i t - \theta^+ + 2k\pi \quad (k = 1, 3, \ldots)$$

(28)

Therefore, to determine the maximum voltage transfer ratio, it is obvious to consider the worst case corresponding to the minimum amplitude of the grid voltage vector. Substituting (27) in (24) the expression of $V_{dc}$ corresponding to this worst case scenario is therefore given by:

$$V_{dc, \text{min}} = \frac{3}{2} E^+ (E^- - E^-) \cos \phi_i$$

(29)

The ripple term in the denominator of (29) is obviously due to the modulation phenomenon of the grid side converter. Therefore the lowest amplitude of $(V_{dc})_{Tc}$ is achieved when the denominator is equal to 1 which yields to:

$$V_{dc, \text{min}} = \frac{3}{2} (E^+ - E^-) \cos \phi_i$$

(30)

It is now evident to conclude that the maximum amplitude of the output voltage fundamental component in the linear region operation can be found by combining equations (30), (26) and substituting $M_i$ by its maximum value $(M_{i,max})$ which yields:

$$V_{\text{omax}} = M_{i,max} \frac{3}{4} (E^+ - E^-) \cos \phi_i$$

(31)

The maximum voltage transfer ratio defined as $q_{\text{max}} = V_{\text{omax}}/E^+$ is thereby deduced from (31) as shown in (32) where $u = E^-/E^+$ is the grid voltage imbalance degree.

$$q_{\text{max}} = \frac{V_{\text{omax}}}{E^+} = M_{i,max} \frac{3}{4} (1-u) \cos \phi_i$$

$$= 0.866 (1-u) \cos \phi_i$$

(32)

If $u = 0$, case of balanced system, one can find the usual $q_{\text{max}}$ value : $q_{\text{max}} = 0.866 \cos \phi_i$

VI. EXPERIMENTAL VALIDATION

A laboratory prototype of an Indirect Matrix Converter connected to unbalanced three-phase voltage sources and feeding a three-phase star-connected RL-load is built to evaluate the performance of the proposed control methodology. A photo of the realized prototype is illustrated in Fig.8. The voltage imbalance is provided using three single-phase autotransformers. Both control and modulation algorithms were fully implemented on the DSP processor TMS 320F28335 of TI with a switching frequency and a sampling rate of 7.5 kHz. The parameters of the experimental setup and controller used in the following tests are detailed in Table I. The average reactive power reference is set to zero ($\omega_{0ref} = 0$).

The performance of the proposed control method is first evaluated under a 15% decrease of one phase amplitude as illustrated in Fig.9a. The distortions observed in the grid voltages waveforms are caused by nonlinear loads connected to the grid. The target output to the input voltage transfer ratio with respect to the positive-sequence amplitude is set to $q = 0.75$ while the load frequency is set to $f_L = 70$ Hz. Fig.9b shows the waveforms of the input filter capacitors voltages. One can observe, in addition to the same voltage imbalance dictated by the grid, high frequency distortion mainly due to the high switching frequency current harmonics flowing into the capacitors.

Figs.10a-b illustrate a phase to neutral output voltage waveform as well as the three load currents. Despite the grid voltage imbalance, the converter is able to provide three-phase balanced and sinusoidal load currents as observed in Fig.10b. The immediate consequence of balancing the load currents/voltages can be observed in the active power waveform shown in Fig.11. The latter is effectively free of double-frequency ripple mainly caused by the grid voltage imbalance. Moreover, except the high-frequency ripple, the obtained active power waveform is almost constant in steady state operation. This result emphasizes the effectiveness of the load side converter’s control methodology as well as the accuracy of the proposed estimator.

On the other hand, Fig.12a shows that the currents injected into the grid (i_a, i_b, and i_c) are effectively sinusoidal and unbalanced. The amplitudes of their fundamental components are 3.15A (i_a), 2.87A (i_b) and 2.94A (i_c) respectively. The THD measured using the power analysis tool found on the scope “Teldyne Lecroy” HD06104-HD4096 is 6.12% for i_a, 6.4% for i_b, and 6.34% for i_c respectively. Moreover, by inspecting Fig.12b, one can observe that the line currents are almost in phase with their corresponding grid voltages i.e. a near unity input power factor is achieved. This interpretation is emphasized by the result of Fig.11 which shows clearly that the average reactive power is very close to zero.

Thus, it can be concluded that the proposed reactive power loop performs a satisfactory steady-state tracking of the reference $Q^{\text{ref}}_R$ which was set to zero. It is also clear that the reactive power waveform includes a ripple component oscillating at twice the grid frequency. This result is quite normal as expected by equation (5) of the theoretical analysis carried out in section II. Note also that only the low-frequency ripple of the active power is removed. Indeed, in the existing control theories applied to converters tied to unbalanced grid voltages, when the constraint of sinusoidal line currents is imposed, therefore, it is not possible to compensate perfectly and simultaneously active and reactive power ripples in case of three-phase three-wire conversion topologies [45].

As in practice, the Indirect Matrix Converter should operate with different output voltages and frequencies; the performance of the proposed methodology is therefore tested for an abrupt change of both q (q changed from 0.75 to 0.55) and $f_o$ ($f_o$ changed from 70 to 50 Hz). Fig.13 shows that the system performs very well during both steady-state and transient operation. Moreover, for the two operating points the line current remains in phase with its corresponding grid voltage.
In Fig. 14 are shown the active and reactive power waveforms. It can be observed that the average value of the reactive power is not affected by the abrupt decrease of the active power and remains very close to zero i.e. the converter remains operating at near unity input power factor.

Since no closed-loop control algorithms were proposed in the earlier literature so as to control the input power factor of IMC operating under unbalanced grid voltages, a comparative study with earlier methods has no meaning. However, in order to show the benefits of the proposed method, the same previous test was carried out without the reactive power loop (the PIR controller and disturbance rejection terms are disabled). Fig. 15 shows clearly that the average reactive power is different from zero for the two operating points.

Obviously, a further decrease of q will lead to a more important variation of the reactive power exchanged with the grid. Therefore, in the absence of the reactive power control loop, when the converter is forced to operate at low value of q, the input power factor may reach lower value, which will definitely have negative impact on the grid.

In a second test, the amplitude of $E_a$ is decreased by 10% while the one of $E_c$ is decreased by 5% as shown in Fig. 16. The result illustrated in Fig. 17 shows clearly that converter is also able to provide balanced current to the load. Moreover, the line currents remain sinusoidal and in phase with their corresponding grid voltages as shown in Fig. 18. Therefore, the unity input power factor operation is also achieved. These results confirm that the proposed reactive power controller and dc-link voltage estimator operate perfectly even under these unfavorable conditions of the grid voltages.

VII. CONCLUSION

This paper introduced an advanced control method for an Indirect Matrix Converter operating under unbalanced grid voltages in order to provide balanced output voltages and achieve a near unity input power factor operation. The benefit of the proposed reactive power controller is the use of a single control loop thanks to the feature of the PIR controller which is able to perform the tracking of both dc and oscillating terms existing in the input current reference. The experimental tests showed that this controller operates very efficiently and confirm its capability to drive the converter with a near unity input power factor even under variable active power demanded by the load. On the other hand, a real-time estimator of the dc-link voltage was successfully constructed based on the instantaneous measurement of grid voltages as well as an average switching function of the grid side converter.
This estimator, which operates downstream of the PIR control loop, allows the converter to provide balanced output voltages and consequently an almost constant active power free of low-frequency ripple supplied from the grid.

APPENDIX

According to (11.2), the expression of $I_{q,ref}^*$ is:

$$I_{q,ref}^* = I^* \sin(\phi_{ref}^*)$$  (A1)

Moreover, the following relationships are derived from equation (10):

$$E^+ = E_d^+$$  (A2)

$$E^{-2} = \left(E_d - E_d^+\right)^2 + E_q^2$$  (A3)

Therefore, reporting (9.2), (A2), and (A3), into (A1) yields equation (12.1). On the other hand, according to (11.2), the expression of $I_{q,ref}$ is:

$$I_{q,ref} = I^* \sin(-2\omega t - \phi^-)$$  (A4)

Reporting (8.1) and (9.2) into (A4) yields:

$$I_{q,ref}^* = \frac{E^+ - E^-}{I^*} \sin(2\omega t + \theta + \phi_{ref}^*)$$  (A5)

Equation (A5) can also be rewritten as follows:

$$I_{q,ref}^* = \frac{1}{E^+ - E^-} \left[ E^+ E_{\sin}(2\omega t + \theta) + I^* E_{\cos}(\phi_{ref}^*) \right]$$  (A6)

Equation (A6) is quite equivalent to (12.1) given in section III/A.

He is presently an Associate Professor of electrical engineering with ISSAT of Sousse, University of Sousse, Tunisia. He is affiliated with Canada Research Chair in Electric Energy Conversion and Power Electronics, “CRC-EECPE”, Ecole de Technologie Superieure (ETS), Montreal, Canada. He is also a member of the research unit SAGE, ENISO, University of Sousse, Tunisia.

His main research interests include renewable energy conversion systems, DSP and FPGA for embedded real time control, unbalanced weak grid systems, development of advanced controllers such as nonlinear control of matrix, multilevel, multicellular, multiphase converters, and grid-tied converters.

**Handy Fortin Blancheet** (S’97–M’10) received the B.Eng., M.Eng., and Ph.D. degrees in electrical engineering from Ecole de Technologie Superieure (ETS), Montreal, PQ, Canada, in 2001, 2003, and 2010, respectively.

From 1994 to 1997, he was engaged in industrial automation. From 1998 to 2000, he was with the Bombardier Transportation-ETS Research Laboratory, Montreal, where he worked on a high power traction system. From 2001 to 2003, he was involved in the development of an electrical drive library for the Simulink (MATLAB) environment. From 2007 to 2010, he was with OPAL-RT Technologies, where he led CPU- and FPGA-based power electronics real-time simulation projects. From 2010 to 2011, he was a Visiting Scholar with the Center for Power Electronic and System, Virginia Polytechnic Institute and State University, Blacksburg, where he was involved in the packaging of high-temperature converters for aircraft applications. He is presently an Associate Professor of electrical engineering with Ecole de Technologie Superieure, Montreal. His current research interests include EMI prediction, circuit modeling, and high density power converter packaging.

Since June 1990, he has been a Professor with the Electrical Engineering Department, Ecole de Technologie Superieure (ETS), Montreal, QC, where he has been the holder of the Canada Research Chair in Electric Energy Conversion and Power Electronics since 2002. He has supervised more than 100 Ph.D. and M.Sc.A. students working in the field of power electronics. He is a Consultant and has established very solid link with many Canadian industries working in the field of power electronics, electric transportation, aeronautics, and telecommunications. He has coauthored more than 500 transactions and conference papers. His fields of interest are in high efficient static power converters, harmonics and reactive power control using hybrid filters, switch mode and resonant converters including the modeling, control, and development of prototypes for various industrial applications in electric traction, electrification and transportation, renewable energy, microgrids, power supplies for drives, telecommunication, etc.
